

MULTIDIMENSIONAL OPTICAL GRATINGS

CROSS-REFERENCE TO RELATED APPLICATIONS

5 This is a continuation-in-part of Application No. 09/953,468, filed September 14, 2001.

TECHNICAL FIELD

10 The present invention relates generally to optical gratings and more particularly to new forms of such gratings capable of diffracting one or more light wavelengths concurrently.

BACKGROUND ART

15 Optical technology is progressing rapidly. Growing needs, particularly in the telecommunications industry, are driving this progress and there is currently a major impetus to improve existing optical systems and to develop new ones. Unfortunately, several major components still are not completely meeting manufacturing yield, field reliability, and operating capacity requirements. These failings have resulted in high costs in existing systems and are limiting the adoption of future systems. One such component is the optical grating.

20 FIG. 1a-b (background art) depict to variations of traditional gratings. As can be seen, the shape of the groove can vary. FIG. 1a shows square steps and FIG. 1b shows blazed triangles, but other shapes are also possible, e.g., sinusoidal shaped grooves, and the physics is essentially the same.

25 Such "traditional gratings" were initially made of glass with grooves, and a few are still produced in this manner today. This, however, has a number of disadvantages. For instance, the density of the grooves is limited by the capability of the ruling engine, and the quality of the grooves produced tends to decrease as elements of the ruling engine wear from usage. Production of this type of gratings is time consuming and difficult, and the cost of such gratings is therefore high.

30 Molded and holographic gratings were invented later on, and their production cost is significantly lower than for glass gratings. Unfortunately, although suitable for many

applications, these gratings tend to deteriorate in harsh environments. For example, in fiber optic communications, all optical components must operate for long periods of time in temperatures ranging from sub-zero to over eighty degrees Centigrade, and in humidity ranging from zero to 100 percent (see e.g., GR-468-CORE, Generic Reliability Assurance Requirements for

Optoelectronic Devices Used In Telecommunications Equipment).

As can also be seen in FIG. 1a-b, traditional gratings have the property that light has to shine on the grating surface from above. This limits the useful diffraction effect of such gratings to only one dimension, and multiple units need to be assembled if multiple dimensions (axes of direction) are required.

One example of an application where the need to work with multiple wavelengths and axes is common, and growing, is wavelength division multiplexing and de-multiplexing (collectively, WDM) in fiber optic communications. The use of traditional gratings in WDM usually requires either adhesives or mechanical fixtures to keep the assembly intact. Alignment is also needed to make sure that the gratings diffract light in the proper directions. The resulting assemblies formed with such traditional gratings thus tend to be significantly larger than the optical fibers being worked with and mechanical connectors are needed for connection. All of these considerations, and others, increase the cost in a fiber optic communications system.

A relatively recent invention is the fiber Bragg grating. The fiber Bragg grating is a periodic perturbation in the refractive index which runs lengthwise in the core of a fiber waveguide. Based on the grating period, a Bragg grating reflects light within a narrow spectral band and transmits all other wavelengths which are present but outside that band. This makes Bragg gratings useful for light signal redirection, and they are now being widely used in WDM.

The typical fiber Bragg grating today is a germanium-doped optical fiber that has been exposed to ultraviolet (UV) light under a phase shift mask or grating pattern. The unmasked doped sections undergo a permanent change to a slightly higher refractive index after such exposure, resulting in an interlayer or a grating having two alternating different refractive indices. This permits characteristic and useful partial reflection to then occur when a laser beam transmits through each interlayer. The reflected beam portions form a constructive interference pattern if the period of the exposed grating meets the condition:

$$2 \cdot \Lambda \cdot n_{\text{eff}} = \lambda$$

where Λ is the grating spacing, n_{eff} is the effective index of refraction between the unchanged and the changed indices, and λ is the laser light wavelength.

FIG. 2 (background art) shows the structure of a conventional fiber Bragg grating 1 according to the prior art. A grating region 2 includes an interlayer 3 having two periodically alternating different refractive indices. As a laser beam 4 passes through the interlayer 3 partial reflection occurs, in the characteristic manner described above, forming a reflected beam 5 and a passed beam 6. The reflected beam 5 thus produced will include a narrow range of wavelengths. For example, if the reflected beam 5 is that being worked with in an application, this separated narrow band of wavelengths may carry data which has been superimposed by modulation. The reflected beam 5 is stylistically shown in FIG. 2 as a plurality of parts with incidence angles purposely skewed to distinguish the reflected beam 5 from the laser beam 4. Since the reflected beam 5 is merely directed back in the direction of the original laser beam 4, additional structure is usually also needed to separate it for actual use.

Unfortunately, as already noted, conventional fiber Bragg gratings and the processes used to make them have a number of problems which it is desirable to overcome. For example, the fibers usually have to be exposed one-by-one, severely limiting mass-production. Specialized handling during manufacturing is generally necessary because the dosage of the UV exposure determines the quality of the grating produced. The orientation of the fiber is also critical, and best results are achieved when the fiber is oriented in exactly the same direction as the phase shift mask. The desired period of the Bragg grating will be deviated from if the fiber is not precisely aligned, and accomplishing this, in turn, introduces mechanical problems. Thus, merely the way that the fiber work piece is held during manufacturing may produce stresses that can cause birefringes to form in the fiber and reduce the efficiency of the end product grating.

Once in use, conventional fiber Bragg gratings may again require special handling. The thermal expansion coefficient of the base optical fiber is often significant enough that changing environmental conditions can cause the fiber to either expand or shrink to the extent that the period of the grating and its center wavelength shift.

From the preceding discussion of traditional and fiber Bragg gratings it can be appreciated that there is a need for optical gratings which are better suited to the growing range of grating applications.

DISCLOSURE OF INVENTION

Accordingly, it is an object of the present invention to provide optical gratings which are improved with respect to the basic ease of use and range of potential uses, and to robustness and reliability once in use.

Briefly, one preferred embodiment of the present invention is an optical grating with a background region of a first material, having a first refractive index, and a grid of cells within the background region. The cells are of a second material having a second refractive index. Optionally, the grid of cells may be extended from two dimensions into a three dimensional grid or lattice of the cells.

An advantage of the present invention is that it provides improved processes to manufacture a variety of optical gratings, particularly including optical gratings able to employ the Bragg effect in multiple dimensions and for up to one light wavelength per such dimension. Thus, for instance a three-dimension or cubical grating according to the present invention may separate light of one, two, or three different wavelengths (or wavelength ranges if "chirping" is also used).

Another advantage of the invention is that it separates such light wavelengths in a more useful way than prior art systems, particularly being able to direct separated narrow-band light wavelengths perpendicular to the paths of the entering beam and any exiting beam of non-separated wavelengths. Furthermore, when multiple light wavelengths are separated, their beams are inherently also widely separated apart.

Another advantage of the invention is that it may employ already well known and widely used manufacturing processes and materials, adopted from conventional electronic semiconductor integrated circuit (IC) and micro electro-mechanical system (MEMS) manufacturing. Highly desirable attributes of such processes may thus be imparted to the inventive processes and the products produced there with, including mass automated manufacturing, rigorous quality control, high yields, and low cost.

Another advantage of the invention, coincident with the above advantage, is that the invention is integratable directly into products by conventional IC and MEMS manufacturing processes. Notable also in this regard, the invention may be constructed of similar size to the devices it may typically be integrated with, and thus avoid the problems attendant with providing

and using connectors, adapters, etc.

Another advantage of the invention is that it does not use fiber based media, thus eliminating a number of disadvantages in both fiber based manufacturing processes and fiber media based grating products.

5 And another advantage of the invention, coincident with the above advantages, is that the invention is economically in comparison to prior art optical gratings.

These and other objects and advantages of the present invention will become clear to those skilled in the art in view of the description of the best presently known mode of carrying out the invention and the industrial applicability of the preferred embodiment as described herein
10 and as illustrated in the several figures of the drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

The purposes and advantages of the present invention will be apparent from the following detailed description in conjunction with the appended figures of drawings in which:

5 FIG. 1a-b (background art) are cross sectional views of two traditional gratings, with depictions of light beams arriving incident to and being redirected by the gratings;

FIG. 2 (background art) is a cross sectional view of a conventional fiber Bragg grating, including a stylized depiction of a laser beam traveling through the grating;

10 FIG. 3 is a cross sectional view of a one-dimensional (1D) or linear Bragg grating, including a stylized depiction of a laser beam traveling through the grating;

FIG. 4a-p are a series of views at different stages of manufacture of one embodiment of a 1D Bragg grating, wherein:

FIG. 4a is a cross section side view of the Bragg grating as a substrate is prepared;

15 FIG. 4b is a cross section side view of the Bragg grating as a layer of photoresist is deposited;

FIG. 4c is a cross section side view of the Bragg grating as it is exposed under a pattern;

FIG. 4d is a top plan view of the Bragg grating after it is exposed;

FIG. 4e is a top plan view of the Bragg grating after a transmissive layer is deposited;

FIG. 4f is a cross section side view of the Bragg grating at the stage in FIG. 4e;

20 FIG. 4g is a top plan view of the Bragg grating after the exposed photoresist is removed;

FIG. 4h is a cross section side view of the Bragg grating at the stage in FIG. 4g;

FIG. 4i is a cross section side view of the Bragg grating after a new layer of photoresist is deposited;

FIG. 4j is a cross section side view of the Bragg grating as it is exposed under a pattern;

25 FIG. 4k is a top plan view of the Bragg grating after it is exposed;

FIG. 4l is a cross section side view of the Bragg grating after the exposed photoresist and portions of the layer below are removed;

FIG. 4m is a top plan view of the Bragg grating at the stage in FIG. 4l;

30 FIG. 4n is a cross section side view of the Bragg grating after a material having a different refractive index than the transmissive layer is deposited;

FIG. 4o is a cross section side view of the Bragg grating after excess material is removed;

and

FIG. 4p is a cross section side view of the Bragg grating after a new transmissive layer is deposited;

FIG. 5a-b are cross section side views depicting laser beams traveling through the finished Bragg grating of FIG. 4a-p, wherein FIG. 5a shows how a beam will travel with minimum loss, and FIG. 5b shows how a beam will encounter constructive interference when the Bragg condition is met;

FIG. 6a-b are cross section side views at different stages of manufacture of a second embodiment of a Bragg grating, wherein FIG. 6a shows the grating after impurities are diffused into a substrate, and FIG. 6b shows the grating after a mask has been applied and additional impurities diffused into the substrate;

FIG. 7 is a flow chart summarizing a process for creating the Bragg grating;

FIG. 8 is a flow chart showing application of the process to create the embodiment of the Bragg grating of FIG. 3;

FIG. 9 is a flow chart showing application of the process to create the embodiment of the Bragg grating of FIG. 5a-b;

FIG. 10 is a flow chart showing application of the process to create the embodiment of the Bragg grating of FIG. 6a-b;

FIG. 11 is a schematic representation summarizing the structure and operation of a one-dimensional (1D) or linear grating, such as the Bragg gratings of FIG. 3-6b;

FIG. 12 is a perspective view showing that the principles of the linear grating of FIG. 11 can be extended to a 2D or planar grating;

FIG. 13 is a perspective view showing that the principles of the linear grating and the planar grating can be further extended to a 3D or cubical grating;

FIG. 14 is a schematic representation of surface-to-surface or intra-cell refraction effects in a grating;

FIG. 15 is a schematic representation of cell-to-cell interference between two vertically adjacent cells in a grating;

FIG. 16 is a schematic representation of cell-to-cell interference between two horizontally adjacent cells in a grating;

FIG. 17 is a schematic representation of general cell-to-cell interference, wherein a

grating contains three cells two in adjacent columns;

FIG. 18 is a schematic representation of the general case of FIG. 17 extended to operate in two dimensions, on two wavelengths, by using non symmetrical relationships in a generic grating;

5 FIG. 19 is a schematic representation of the non symmetrical generic grating of FIG. 18 as it might typically be applied in an actual planar or cubical grating according to the present invention; and

FIG. 20 is perspective view of a three-dimensional (3D) generic grating.

BEST MODE FOR CARRYING OUT THE INVENTION

Preferred embodiments of the present invention are multidimensional optical gratings, particularly including a two-dimensional (2D) variation which will herein be termed a "planar grating" and a three-dimensional (3D) variation which will herein be termed a "cubical grating."

A basic narrow bandwidth Bragg type grating, that is a one-dimensional (1D) or a "linear grating," is used as the primary example for an initial discussion of manufacturing techniques that may be employed for 1D, 2D, and 3D variations of the gratings. Linear gratings and such manufacturing techniques, generally, are the subject of the present inventors' co pending patent application 09/953,468, hereby incorporated by reference in its entirety.

As illustrated in the various drawings herein, and particularly in the views of FIG. 12 and 13, the 2D preferred embodiment of the invention is depicted by the general reference character 600 and the 3D preferred embodiment of the invention is depicted by the general reference character 700.

FIG. 3 is a cross sectional view depicting a one-dimensional (1D) or linear Bragg grating 100, with a laser beam 102 stylistically represented as traveling through it. The Bragg grating 100 includes a substrate 104, atop which the major operational elements have been constructed. The substrate 104 may be a material such as silicon wafer, glass plate, etc. A reflective layer 106 has been deposited atop the substrate 104. Suitable materials for this include inherently reflective ones, such as metallic coatings like gold, silver, or aluminum, as well as materials having a low refractive index relative to the refractive indices of the materials in a grating region (described next).

A grating region 108 is provided atop the reflective layer 106. Various materials and manufacturing techniques may be used to construct this grating region 108 and, in fact, a substantial part of the following discussion covers such variations. For purposes of this introduction, the grating region 108 can be viewed simply as including an interlayer 110 of regions of a first transmissive material 112 and a second transmissive material 114. The first transmissive material 112 and second transmissive material 114 have different refractive indices and are interspaced by one-quarter of the wavelength of light which the Bragg grating 100 will filter (or by an odd numbered multiple of one-quarter wavelength).

An over-fill layer 116 is provided atop the grating region 108. It may be a material

having a different refractive index, relative to the refractive indices of the other materials in the grating region **108**, it may be additional of the transmissive materials **112**, **114** (as is shown here), or it may be a metallic coating similar to the reflective layer **106** used for similar purposes below the grating region **108**.

5 Operationally, the Bragg grating **100** receives the laser beam **102** in the manner shown in FIG. 3. [For simplified explanation, "laser beam" is used herein as a generic term to represent all suitable light beams. Although light from laser sources is today predominantly used in applications where the Bragg grating **100** will be widely employed, those skilled in the art will readily appreciate that light from other sources may be used as well.] The reflective layer **106**
10 serves to reflect strayed portions of the laser beam **102** back in the original direction. Similarly, the over-fill layer **116** also does this. Here the over-fill layer **116** is of the same material as the second transmissive material **114** and it reflects the laser beam **102** because its index of refraction is substantially higher than that of the surrounding air.

15 As the laser beam **102** passes through the interlayer **110** of the grating region **108** it encounters the boundaries between the first and second transmissive materials **112**, **114**. In particular, it encounters the respectively different refractive indices there. Partial reflection then occurs as the laser beam **102** passes through each boundary, forming a reflected beam **118** and a passed beam **120**. [The reflected beam **118** is stylistically shown in FIG. 3 as a plurality of parts with incidence angles purposely skewed to distinguish the reflected beam **118** from the laser beam **102**.] The reflected beam **118** will include a narrow range of wavelengths, formed in the
20 characteristic manner of the Bragg condition by constructive interference in the light that is reflected, and the passed beam **120** includes the light of other wavelengths that were also present in the laser beam **102**.

25 FIG. 4a-p are a series of views at different stages of manufacture of one of a presently preferred embodiments of the Bragg grating **100**. FIG. 4a is a side view of a substrate **202**. As already noted, the substrate is of a suitable material upon which the major operational elements are constructed. At this initial stage the substrate **202** is essentially homogeneous. FIG. 4b is a side view after a photoresist layer **204** has been deposited atop the substrate **202**.

30 FIG. 4c is a side view as the Bragg grating **100** is exposed. A photomask **206** having a pre-designated pattern **208** is provided and the Bragg grating **100** is exposed through it to light **212** which is appropriate for causing a photochemical reaction in the photoresist layer **204**. This

produces an unexposed region **204a** and an exposed region **204b**. FIG. 4d is a top view of the Bragg grating **100** after exposure, particularly depicting the unexposed region **204a** and the exposed region **204b**. Typically these would be termed to now have negative resist and positive resist, respectively.

5 FIG. 4e is a top view of the Bragg grating **100** after a transmissive layer **214** is deposited. As can be seen, some of the unexposed region **204a** and some of the exposed region **204b** of the photoresist layer **204** are left uncovered at this stage. FIG. 4f is a side view at this stage. The transmissive layer **214** has a thickness exceeding the height of light beams with which the Bragg grating **100** will later be used. In the inventor's presently preferred embodiment SiO₂ is used for
10 the transmissive layer **214**. This material is easily "worked" as needed and its refractive index, of nominally 1.52, is also good. Many other materials may also be used, however. Without limitation, other suitable candidates which are widely used industrially are Al₂O₃, with a refractive index of 1.63, and MgF₂, with a refractive index of 1.38. [Still other candidates include amorphous silicon-hydrate (SiH, SiH₂, SiH₃, SiH₄), B, P, ZnSe, ZnS, GaP, SrTiO₃, Si, Ge, InSb, YSZ, AlAs, BaTiO₃, BiSiO₂₀, Bi₁₂GeO₂₀, AlN, BN, AgGaS₂, LiTaO₃, CuCaS₂, TlI, TlCl, TlBr, AgCl, AgBr, AgI, AgGaSe₂, K₂NbO₃, and even some organic materials.]

The unexposed region **204a** remains once the exposed region **204b** is removed (via any of various conventional means, chemical etching, dry etch techniques, subliming by baking, etc.). FIG. 4g is a top plan view and FIG. 4h is a side view of the Bragg grating **100** after
20 removal. As can particularly be seen in FIG. 4h, removing the exposed region **204b** leaves an air gap **216** between the substrate **202** and the transmissive layer **214**. [Note, the "air gap" here may ultimately contain any gas present in the environment surrounding the Bragg grating **100**. The inert gasses, N₂, CO₂, air, other gas mixtures, etc. are examples of gases commonly used in electronic equipment today. For that matter, the "air gap" can even be a vacuum. As will be seen
25 in the operational discussion, below, the index of refraction of the air gap is what is key, and not what fills it.]

FIG. 4i is a side view of the Bragg grating **100** after a new photoresist layer **218** has been deposited, and FIG. 4j is a side view as it is exposed. A photomask **220** having a grating pattern **222** is here provided and the Bragg grating **100** is exposed through it to light **224**. This produces
30 an unexposed region **218a** and a plurality of exposed regions **218b**. FIG. 4k is a top view of the Bragg grating **100** after it is exposed in this manner, particularly showing the unexposed region

218a and the exposed regions **218b**.

FIG. 4l is a side view of the Bragg grating **100** after the exposed regions **218b** of the photoresist layer **218** and portions of the transmissive layer **214** below it have been removed. In FIG. 4l the unexposed region **218a** is also shown as having already been removed. A key point to note, for this manufacturing variation, is that portions of the transmissive layer **214** are not removed so deeply that the air gap **216** is reached. The reason for this is provided in an operational discussion, below. FIG. 4m is a top view of the Bragg grating **100** at this stage. From FIG. 4l and FIG. 4m it can be appreciated that an array of open trenches now defines the grating region **226** in the transmissive layer **214**.

FIG. 4n is a side view of the Bragg grating **100** after an over-fill layer **228** is deposited into the array of trenches. The over-fill layer **228** is of a material having a slightly different refractive index than the transmissive layer **214**, and it fills in the openings grating region **226** so that a linearly extending interlayer array **230** is formed. The material of the over-fill layer **228** may be one of the same set of candidate materials for the transmissive layer **214**, e.g., Si, SiO₂, Al₂O₃, MgF₂, etc., but it will either be of a different such material or, if the same, it will be treated to achieve a different refractive index.

FIG. 4o is a side view of the Bragg grating after excess material from the over-fill layer **228** has been removed. One process suitable for this is polishing. The unexposed region **218a** was shown as having been already removed in FIG. 4l, but it could alternately have been left, the over-fill layer **228** applied atop it, and then it and the excess from the over-fill layer **228** removed together. In some manufacturing scenarios this is a matter of mere choice, but in others there may be an incentive to remove the over-fill layer **228** earlier. For instance, in common semiconductor fabrication processes organic photoresist materials are used. These are generally suitable for use here as well, but with early removal desirable to avoid contaminating the over-fill layer **228** as it is later applied.

Finally, FIG. 4p is a side view of the Bragg grating **100** after a new transmissive layer **232** is deposited. In this embodiment the inventors prefer that the transmissive layer **214** and the transmissive layer **232** have the same refractive index, and thus that they be of the same material. This is not a requirement, however. The transmissive layer **232** may, for instance, be of the same material and have the same refractive index as the over-fill layer **228**. As will become more clear in the discussion below, it is desirable that the over-fill layer **228** have a refractive index

substantially different than that of air (refractive index = 1). Thus a material like, say, MgF₂ with a refractive index of 1.38, may be quite suitable for use in the over-fill layer **228** but not in the transmissive layer **232**. This completes construction of the Bragg grating **100**.

FIG. 5a-b are cross section side views depicting a light beam **240** traveling through the finished Bragg grating **100** of FIG. 4a-p. In FIG. 5a the light beam **240** has strayed portions **242**, some of which go upward and others of which go downward. The downward traveling of the strayed portions **242** encounter an interface **244** at the juncture of the transmissive layer **214** and the air gap **216**, and are reflected back into the transmissive layer **214**. Similarly, the upward traveling of the strayed portions **242** encounter an interface **246** at the juncture of the transmissive layer **232** and the air above the Bragg grating **100**, and are reflected back into the transmissive layer **232**. Thus the interface **244** created at the air gap **216**, and the disparity between the refractive indices, is used to achieve reflection. This is structurally different than the embodiment of FIG. 3, where the reflective layer **106** was deposited below the grating region **108**, but it is functionally equivalent. The light beam **240** is thus here also able to travel through the Bragg grating **100** with minimum power loss.

FIG. 5b shows how the main portion of the light beam **240** encounters the interlayer array **230** in the grating region **226**, how a reflected portion **248** (stylistically shown here also as a plurality of parts with purposely skewed incidence angles) is created, and how a passed portion **250** is passed. The reflected portion **248** will include a narrow range of wavelengths, formed by constructive interference, and the passed portion **250** will include the light of other wavelengths that are also present in the light beam **240**.

FIG. 6a-b are side views at different stages of manufacture of a second embodiment of a Bragg grating **100**. FIG. 6a shows the Bragg grating **100** in an early stage of manufacture, after a substrate **302** has had impurities diffused into a grating region **304**. FIG. 6b shows the Bragg grating **100** in a later stage of manufacture, after a mask **306** having a suitable open grating pattern **308** has been applied and additional impurities have been diffused into the grating region **304** below the openings in the grating pattern **308** to form a linearly extending interlayer array **310**. The Bragg grating **100** here can then be finished, in straightforward manner, by removing the mask **306** and applying an over-fill layer (not shown).

This approach employs the fact that the refractive indices for certain materials will change when impurities are diffused into them. One well known example is silicon: the

refractive index for pure silicon is 3.5 but reduces to as low as 2.1 when a heavy dosage of hydrogen is diffused into it. The refractive index can further be reduced to even lower than 1.5 by incorporating different levels of oxygen. Another example material is silica (SiO_2): when it's diffused with germanium and under exposure of UV light its refractive index increases slightly.

5 The Bragg grating **100** depicted in FIG. 6a-b can thus take advantage of these properties to obtain the desired characteristics in the interlayer array **310**.

FIG. 7 is a flow chart summarizing a process **400** for creating the Bragg grating **100**. The process **400** starts in a step **402**, where basic and conventional set up operations can be performed, as needed and as desired.

10 In a step **404** a substrate is provided and prepared. This serves as the basis of a workpiece for the rest of the process **400** and for construction of the Bragg grating **100**.

In a step **406** a lower reflective means is constructed.

In a step **408** a grating region having an interlayer is constructed.

In a step **410** an upper reflective means is constructed.

15 Finally, in a step **412** the process **400** ends. This is where basic and conventional wrap up operations can be performed, as needed and as desired. The process **400**, which in deed has been described very generally, is now finished.

20 FIG. 8 is a flow chart showing application of the process **400** to create the Bragg grating **100** of FIG. 3. The conventional or straightforward step **402** (start) and step **404** (substrate preparation) again occur. The step **406** (constructing a lower reflective means) here includes a single sub-step **422** for providing a reflective layer, such as a metallic coating, onto the (substrate) workpiece.

25 The step **408** (constructing the grating region and interlayer) here includes a number of sub-steps. The first of these is a sub-step **424** to provide a first transmissive layer on the workpiece, atop the reflective layer. In a sub-step **426** a first photoresist layer is then provided on the workpiece, atop the first transmissive layer. In a sub-step **428** the workpiece is exposed under a photomask. The photomask particularly has a pattern as already described, e.g., for a simple Bragg grating a pattern interspaced by one-quarter of the wavelength (or by an odd numbered multiple of that) of the light which will be filtered.

30 In a sub-step **430** the exposed portions of the first photoresist layer are removed. Underlying portions of the first transmissive layer are also removed to a desired depth.

In a sub-step **432** a second transmissive layer is applied to the workpiece, atop the unetched portions of the first photoresist layer and filling in the first transmissive layer. The second transmissive layer particularly has a different index of refraction than the first transmissive layer.

5 In a sub-step **434** excess material, that is the upper most material here, is removed from the workpiece. Specifically, the second transmissive layer and unetched portions of the first photoresist layer are removed to a depth at least flush with the top most portions of the first transmissive layer. This completes the step **408** (grating region and interlayer construction).

10 The step **410** (constructing the upper reflective means) here includes a single sub-step **436** for providing a third transmissive layer on the workpiece, atop the remaining first and second transmissive layer portions. This third transmissive layer has the same index of refraction as the first or second transmissive layer. In a final step **412** the process **400** is now finished.

15 FIG. 9 is a flow chart showing application of the process **400** to create the Bragg grating **100** of FIG. 5a-b. The conventional or straightforward step **402** (start) and step **404** (substrate preparation) again occur.

20 The step **406** (constructing a lower reflective means) here includes a number of sub-steps. The first of these is a sub-step **438** to provide a first photoresist layer on the (substrate) workpiece. In a sub-step **440** the workpiece is exposed under a first photomask. In a sub-step **442** a first transmissive layer is provided on the workpiece, atop the first photoresist layer. In a sub-step **444** the exposed portion of the first photoresist layer is removed, leaving an air gap between the substrate and the first transmissive layer.

25 The step **408** (constructing the grating region and interlayer) here also includes a number of sub-steps. In fact, in this variation on the process **400** the sub-steps **442**, **444** are part of both step **406** and step **408**. The rest of the step **408** continues with a sub-step **446** where a second photoresist layer is applied to the workpiece, atop the first transmissive layer. In a sub-step **448** the workpiece is exposed under a second photomask having a suitable pattern.

In a sub-step **450** the exposed portions of the second photoresist layer and the underlying first transmissive layer are removed to a desired depth. This leaves an array of openings or trenches.

30 In a sub-step **452** a second transmissive layer is applied to the workpiece, atop the unetched portions of the second photoresist layer and filling in the trench array in the first

transmissive layer. This second transmissive layer has a different index of refraction than the first transmissive layer.

In a sub-step **454** the upper most material, specifically the second transmissive layer and unetched portions of the second photoresist layer, is removed to a depth at least flush with the top most portions of the first transmissive layer. This completes the step **408** (grating region and interlayer construction).

The step **410** (constructing the upper reflective means) here includes the single sub-step **436** for providing a third transmissive layer on the workpiece, atop the remaining first and second transmissive layer portions. This can be essentially the same as the step **410** and sub-step **436** of FIG. 8. In a final step **412** the process **400** is now finished.

FIG. 10 is a flow chart showing application of the process **400** to create the Bragg grating **100** of FIG. 6a-b. The conventional or straightforward step **402** (start) and step **404** (substrate preparation) again occur.

The step **406** (constructing a lower reflective means) here may be viewed as a variation of the approach used for step **410** in FIG. 8 and FIG. 9, or as a variation of the approach used for step **406** FIG. 9. A lower reflector is formed by the interface of the material of the substrate with air or another material below the substrate. As discussed, below, the grating region need not extend all the way down and through the substrate, and the excess material in the substrate thus can serve as part of the lower reflector. In this regard, step **404** and step **406** are essentially merged. Alternately, a reflective material can be applied, similar to the reflective coating used in sub-step **422** in FIG. 8.

The step **408** (constructing the grating region and interlayer) here includes a number of sub-steps. The first of these is a sub-step **456** to dope a portion of the substrate (or a first transmissive layer atop a substrate) which will ultimately become the grating region with an impurity. In a sub-step **458** a mask is constructed on the workpiece, atop the grating region. In a sub-step **460** an additional or other impurity is doped into the non-masked portions of the grating region. In a sub-step **462** the mask is removed.

The step **410** (constructing the upper reflective means) here may include the approach shown in FIG. 8 for step **406**, using sub-step **422**, or it may include the approach shown in FIG. 8 and FIG. 9 for step **408**, using sub-step **436**. Finally, in a step **412** the process **400** is finished. It is, however, a straightforward extension of the process **400** to use multiple iterations of the

various steps, to construct the sophisticated variations on the Bragg grating **100** which are now described.

With reference back to the earlier figures, more than two transmissive materials can be placed into the path a light beam will encounter. In FIG. 5b two materials having two indices of refraction are present in the transmissive layer **214** and in the interlayer array **230**. In FIG. 6b, the substrate **302** is one material having one index of refraction, and the interlayer array **310** is effectively of two other materials (after it is doped or has impurity diffused into it). Even variations on the Bragg grating **100** like those in FIG. 3, FIG. 5a-b, and FIG. 6a-b are relatively simple, and the true scope of the invention is much broader. It is a straightforward extension of the process **400** to use multiple materials (actual different materials or effectively so by treatment to change the indices of refraction). One reason to do this is to handle multiple frequencies in a light beam, or to broaden the bandwidth of the frequencies filtered. Similarly, the spacing of the regions in the interlayers **110**, **230**, **310** can be changed to do this, much in the manner of periodically "chirped" prior art Bragg gratings.

One sophisticated manufacturing technique which may be used is to tune the indices of refraction. For instance, amorphous silicon-hydrate (SiH , SiH_2 , SiH_3 , SiH_4) can be "tuned" by temperature. This can be used to obtain specific desired indices of refraction, or to apply a gradient in the indices in one or more materials. In this manner, the index of refraction is another factor which can be controlled during grating fabrication to achieve chirped or other sophisticated grating types.

FIG. 11 is used next to summarize the one-dimensional (1D) or linear grating. FIG. 12 and 13 then help in an introduction illustrating that the principles of the one-dimensional (1D) or linear grating can be extended to provide a two-dimensional (2D), planar grating, and also a three-dimensional (3D), cubical grating. FIG. 14-17 support derivations extending the principles to the multidimensional, 2D and 3D cases. And FIG. 18-20 depict how gratings having multiple dimensions may have different optical properties relative to each such dimension.

FIG. 11 depicts the structure and operation of a 1D or linear grating **500** (e.g., any of the variations of the Bragg grating **100** already discussed). The linear grating **500** is made of at least two different transparent materials. One of these serves as a background material **502** and one or more others are interlayer materials, with multiple regions of one interlayer material **504** represented here.

The diffraction efficiency in the linear grating **500** depends on the effective refractive index of the particular interlayer material **504** and the background material **502**. The simplest case is depicted in FIG. 11, where just two materials are employed having refractive indices of n_1 and n_2 . The background material **502** can have either n_1 or n_2 , depending on manufacturing convenience, and here it has arbitrarily been made n_1 .

The regions of the interlayer material **504** (n_2) are provided with a thickness **506** such that the phase difference between the reflecting portions of a light beam from both surfaces of a region are multiples of 360 degrees. This insures that constructive interference for a specific wavelength can occur. A similar rational, achieving constructive interference, applies to providing a separation **508** between the regions of the interlayer material **504**.

In operation, a light beam **510** may be directed into the linear grating **500**, as shown in FIG. 11, to form a reflected beam **512** (shown here skewed for emphasis) and a passed beam **514**. The reflected beam **512** will contain the light of the specific wavelength for which constructive interference occurs, and the passed beam **514** will contain all other wavelengths. Thus, the linear grating **500** can be used as a filter to obtain light of high wavelength purity. Alternately, in the manner of prior art gratings, the thicknesses **506** and the separations **508** of the regions of the interlayer material **504** may be varied to "chirp" the linear grating **500** and thereby broaden the reflected beam **512** to include a range of wavelengths.

FIG. 12 is a stylized perspective view showing that the principles of the linear grating **500** of FIG. 11 can be extended to a 2D or planar grating **600**. The planar grating **600** has a background **602** containing a grid of cells **604**. The background **602** has a refractive index, say, n_1 , and the cells **604** have at least one different refractive index. For simplicity in this discussion, the cells **604** are all of the same material and refractive index, say, n_2 .

In FIG. 12 an XYZ-axes icon **606** shows a standard Cartesian reference scheme used to facilitate this discussion. The cells **604** have a respective thickness **608** and separation **610** along the X-axis, and also a respective thickness **612** and separation **614** along the Y-axis. These can be chosen in much the same manner as the thickness **506** and the separation **508** of the linear grating **500**. Furthermore, if desired, the respective sets of these may be chosen to be different, to obtain constructive interference for different specific wavelengths (discussed in more detail, presently).

FIG. 12 also includes stylized representations of a light beam **616**, a diffracted beam **618**,

and a passed beam **620**, to depict how the planar grating **600** employs constructive interference in the XY-plane. The light beam **616** may contain a number of light wavelengths, including one which meets the Bragg condition for the thicknesses **608**, **612**, separations **610**, **614**, and refractive indices here. The diffracted beam **618** will then contain only light of the wavelength meeting the Bragg condition provided for, while the passed beam **620** will contain the other wavelengths present.

FIG. 13 is a stylized perspective view showing that the principles of the linear grating **500** and the planar grating **600** can be further extended to a 3D or cubical grating **700**. The cubical grating **700** has a background **702** containing a grid of cells **704**. The background **702** has a particular refractive index and the cells **704** have one or more other refractive indices. For simplicity, the cells **704** here are all of the same material.

In FIG. 13 an XYZ-axes icon **706** shows a standard Cartesian reference scheme used to facilitate this discussion. The cells **704** have respective thicknesses along the X-axis, Y-axis, and Z-axis, and also respective separations along each of these axes. If desired, these respective dimension sets may also be chosen to be different, to obtain constructive interference for different specific wavelengths. That is the case here and two of the three possible sets of thicknesses and separations have been chosen to be different.

FIG. 13 also includes stylized representations of a light beam **708**, a first diffracted beam **710**, a second diffracted beam **712**, and a passed beam **714**. The cubical grating **700** here employs one condition of constructive interference in the XY-plane as well as a second condition of constructive interference in the ZX-plane. The light beam **708** may contain a number of light wavelengths, including two which meet the respective Bragg conditions designed for here. The first diffracted beam **710** will thus contain the light wavelength subject to diffraction in the XY-plane, the second diffracted beam **712** will thus contain the light wavelength subject to diffraction in the YZ-plane, and the passed beam **714** will contain the other wavelengths. This is now explained in further detail in a coverage of the principles underlying the inventive planar grating **600** and the inventive cubical grating **700**.

Turning now to derivations of how the principles in one dimension extend to multiple dimensions, FIG. 14 illustrates cell interference (based on intra-cell refraction) in a generic grating **800**. A background **802** is provided having a refractive index n_1 , and is shown here with a single cell **804** (potentially one of many which may be present in embodiments of planar or

cubical gratings according to the present invention). The cell **804** is of a material having a different refractive index, n_2 , and it has a thickness **806** (d).

When a light beam **808** (carrying a wavelength λ) travels through the background **802** (medium n_1) and shines on a first surface **810** of the cell **804** at an incidence angle θ_1 , a first reflected portion **812** (of the light beam **808**) is produced and reflected from the cell **804**, as shown. Concurrently, as similarly occurs in the linear grating, the rest of the light beam **808** transmits into the cell **804** (medium n_2) as a first refracted portion **814**. This first refracted portion **814** is refracted at the first surface **810** according to the law of refraction, or Snell's law:

$$n_1 \sin \theta_1 = n_2 \sin \theta_2,$$

where θ_2 is the refracted angle in the cell **804**. The first refracted portion **814** then travels through the cell **804** until it encounters a second surface **816** of the cell **804**, where part of it is reflected as a second reflected portion **818** and the rest exits the cell **804** as a transmitted portion **820**.

The second reflected portion **818** travels back to the first surface **810**, where it is refracted back into the background **802** as a second refracted portion **822**. This second refracted portion **822** constructively interferes with the first reflected portion **812** if the thickness **806** (d) and the refracted angle θ_2 satisfy the condition (based on Bragg's law):

$$\text{Eq. 1:} \quad 2n_2 d \cos \theta_2 = k\lambda,$$

where k is an integer.

The transmitted portion **820** simply exits the cell **804** and continues to propagate in the original direction of the light beam **808**, potentially to encounter and interact with another cell, and repeat the phenomenon.

It follows that by design with proper values for n_1 , n_2 , d , and the incidence angle θ_1 , that portions of the light beam **808** can be made to constructively interfere and, in a grating constructed accordingly, the cells will behave like scatterers, to scatter light beams in a designated direction.

On the other hand, there also exists the possibility of cell-to-cell interference. In order to employ this to also achieve constructive interference between adjacent cells, certain conditions also have to be met. FIG. 15 depicts cell-to-cell interference between two vertically adjacent cells, and FIG. 16 depicts cell-to-cell interference between two horizontally adjacent cells.

Turning first to FIG. 15, it depicts the generic grating **800**, again, with the background **802**, but now containing a lattice of two of the cells **804** which are vertically aligned. The

reflected intensity will be maximum if the optical path difference (OPD_v) between the cells **804** meets the condition:

$$\text{OPD}_v = 2*\delta_1 = 2*n_1*b*\cos \theta_1 = m*\lambda,$$

where δ_1 is the distance shown, b is a vertical separation **826** between the two adjacent cells, and m is an integer.

Turning next to FIG. 16, it similarly depicts the generic grating **800**, only now with the background **802** containing a lattice of two of the cells **804** which are horizontally aligned. The reflected intensity here will be maximum if the optical path difference (OPD_h) between the cells **804** meets the condition:

$$\text{OPD}_h = \delta_1 - \delta_2 = 2*n_1*a*\sin \theta_1 = l*\lambda,$$

where δ_1 and δ_2 are the distances shown, a is a horizontal separation **828** between the two adjacent cells, and l is an integer.

FIG. 17 depicts a general case for cell-to-cell interference, wherein the generic grating **800** now contains three cells **804**, in adjacent columns. The reflected intensity will be maximum if the optical path difference (OPD) between these cells **804** meets the condition:

$$\text{Eq. 2:} \quad \text{OPD} = \delta_1 - \delta_2 = 2*n_1*(a^2 + c^2)^{1/2}*\cos(\phi - \theta_1) = m*\lambda,$$

where δ_1 and δ_2 are the distances shown, a is the horizontal separation **828** between two adjacent cells, b is the vertical separation **826** between the two adjacent cells, c is a vertical separation **830** between two cells in adjacent columns, ϕ is the angle shown (essentially, a measure of cell-to-cell dis-alignment relative to the incidence surfaces), θ_1 is the angle of light beam incidence, and m is an integer.

FIG. 18 depicts the general case of FIG. 17 extended to operate two dimensionally, on two wavelengths by using non symmetrical relationships in a grating **850**. A background **852** (having refractive index n_1) here contains three cells **854** (having refractive index n_2). The cells **854** have a horizontal thickness **856** (x), a vertical thickness **858** (y), a horizontal separation **860** (a), a first vertical separation **862** (e), and a second vertical separation **864** (f). A light beam, stylistically represented as first portions **866** having a first wavelength λ_1 and second portions **868** having a second wavelength λ_2 , approaches the cells **854**. The first portions **866** are then scattered as shown if Eq. 2 is satisfied with respect to θ_1 . Similarly, the second portions **868** are scattered as shown if Eq. 2 is satisfied with respect to θ_2 .

FIG. 19 is a diagram of the grating **850** of FIG. 18 as it might typically be applied in an

actual planar or cubical grating according to the present invention. Since the "pitch" of each grating cell-surface determines a "resonance" wavelength, by varying the pitch and the cell spacing in a two-dimensional grating an incoming multiple-wavelength laser beam can be sorted into single-wavelength beams in a spatial domain. Since the parameters of each individual grating unit can be made accurately with semiconductor-like manufacturing process, the directions of each single-wavelength laser beam can be made parallel, for use in ultimate applications.

FIG. 20 is perspective view of a three-dimensional (3D) grating **880**. In the grating **880** a background material (not shown, but of a material having refractive index n_1) contains non symmetrical cubic cells **882** (of a material having refractive index n_2). An incoming light beam including three wavelengths $\lambda_1, \lambda_2, \lambda_3$, stylistically represented as first portions **884**, second portions **886**, and third portions **888**, is incident to the cells **882** on their surfaces. With respect to each of the three different incident surfaces and opposed surface sets, the cells **882** each behave like a "scatterer" according to Eq. 1 and 2, above.

Firstly, with respect to Eq. 1, the light wavelengths are each respectively scattered by a different set of opposite surfaces if:

$$2 \cdot n_2 \cdot d_i \cdot \cos \theta_i = m_i \cdot \lambda_i,$$

where d_i is the respective cell thickness perpendicular to the "scattering" surface, θ_i is the respective refracted angle inside the cell, and m_i is an integer respectively in each dimension. In fact, λ_i can be viewed as the "inter-cell resonant wavelength" for opposite cell surfaces optically separated by d_i .

Secondly, with respect to Eq. 2, the light wavelengths are each respectively scattered by a different incident surface if:

$$OPD_i = 2 \cdot n_1 \cdot a_i \cdot \cos (\phi_i - \theta_i) = m_i \cdot \lambda_i,$$

where OPD_i is the optical path difference between the cell-to-cell incident surfaces, a_i is the cell-to-cell separation, ϕ_i is the angle of cell-to-cell dis-alignment (relative to the incidence surfaces), θ_i is the angle of light beam incidence to the incidence surfaces, and m_i is an integer.

There are a number of factors which provide the present invention with its novel abilities. For constructing the invention, these may be tailored individually or collectively, and the following, without limitation, now discusses some of these factors.

The background material's index of refraction (n_1) can be considered by itself. While

many embodiments will intentionally keep this constant throughout the grating, it can also be controlled to craft sophisticated embodiments of the invention. Using micro-fabrication techniques it is a simple matter to make different regions of the background material have different indices of refraction. Conceptually, this is can be viewed as constructing a number of contiguous gratings. It is useful to work with multiple light wavelengths in the gratings. More complex micro-fabrication techniques, however, also permit making all, or one or more parts, of the background material have indices of refraction which vary. For instance, a gradient can be imposed by controlled doping during grating fabrication. This permits constructing gratings that work with a range of light wavelengths (somewhat analogous in effect to conventional chirped gratings).

In multi-dimensional contexts such a gradient need not extend merely in a single-dimensional, lengthwise manner, like the light beam **510** progressing through the linear grating **500** in FIG. 11. For example, if the index of refraction were varied from, say, the top-left corner to the bottom-right corner in the linear grating **850** in FIG. 19, the first portions **868** (λ_1) and the second portions **868** (λ_2) would both contain broadened wavelength response (i.e., each be "chirped"). Similarly, if the index of refraction were varied from corner to corner in the cubical grating **880** of FIG. 20, the three respective portions **884**, **886**, **888** (λ_1 , λ_2 , λ_3) there would each be wavelength broadened.

Next the cell material's index of refraction (n_2) can be considered by itself. Again, sophisticated embodiments of the invention can be constructed by working with the index of the material here. Constructing the cells using different single-index materials permits making gratings that work with multiple light wavelengths. Here that capability can be also particularly well integrated into the grating as a whole. FIG. 12 and the planar grating **600** depicted there can help illustrate this. The right-most cells **604** might have index n_{2a} , the middle-most cells have a different index n_{2b} , the left-most cells again have index n_{2a} , (and so forth in the many, many "layers" in most practical embodiments). The diffracted beam **618** will then contain two wavelengths, (λ_a , λ_b). Alternately, the cells **604** by index (n_{2a} , n_{2b}) can be arranged other than by layers. They can even be placed randomly. The ratio of cells **604** having index n_{2a} to those having index n_{2b} can also be varied, to "strongly" separate one wavelength (say, λ_a) and less completely extract the other (λ_b). Of course, the invention is not limited to just cells having two indices (n_{2a} , n_{2b}); a third (n_{2c}), fourth (n_{2d}), etc. are possible as well. Similarly, once the concept

is grasped for two-dimensions, it follows that it can be also be employed in three (consider FIG. 13 and the cubical grating 700 there).

Constructing the cells using internally varying material indices is also possible. This is another way to construct gratings that work with ranges of light wavelengths (again, somewhat analogous in effect to conventional chirped gratings, but here potentially with respect to each grating-dimension).

Next consider the background and cell material's indices of refraction together (n_1 and n_2). These two indices may be viewed as one factor, an "effective index" or "relative index" that effects the overall efficiency of the grating. Additionally, these indices can be worked with to facilitate construction. If one material (say, n_2) is hard to hold constant or to vary the characteristics of during grating fabrication, the other (n_1) can be worked with instead. It should also be noted that $n_1 < n_2$ or $n_1 > n_2$ can be used.

The surface-to-surface dimensions of the cells can also be considered. If the cells are made very small, comparable to the wavelength of the light source. Then the surface-to-surface dimensions are not a factor and Bragg's law can apply directly. Alternately, as has been shown above, the cells can be made larger. In this case, Bragg's law can still apply if one or more cell "thickness" is made so that the reflected waves constructively interfere.

As shown in FIG. 14, 18, and 20, the cells can have one, two, or even three different thickness, to effect a corresponding number of light wavelengths differently. Furthermore, in sophisticated embodiments these respective cell thickness can intentionally be different. To help appreciate this further, reconsider the above discussion about varying cell index of refraction. Cell to cell variation can be employed. Finite sets or ranges of thicknesses for the different cells can be used; the cells so constructed can be placed in layers, another ordering, or randomly; and the proportions between the different cells can cells equal or otherwise, to purposely work more or less strongly with particular light wavelengths.

The cell-to-cell spacings can likewise be considered. As shown in FIG. 15, the row-to-row placement of the cells can be controlled (to achieve uniformity or intentional forms of "non-uniformity," like the examples noted above). Similarly, as shown in FIG. 16, the column-to-column placement of the cells can be controlled (again for uniformity or intentional non-uniformity). Furthermore, however, as shown in FIG. 17, the cell-to-cell placement can be asymmetric. Either row-to-row asymmetry, column-to-column asymmetry, or both can be used.

Still further, although semantically somewhat an oxymoron, this asymmetry can be uniform or non-uniform. For example, any or all of the separations **826**, **828**, **830** can be held constant or varied.

The cell quantity present is also a factor meriting consideration. If a large grating with
5 may cells is cut into slices, Bragg's law holds for each. If only two rows, columns, etc. of cells are involved, the transition from constructive to destructive interference is quite gradual. In contrast, if many cells are present, the constructive interference will peak very sharply, with mostly destructive interference in between the peak wavelengths. In fact, this sharpening of the peaks is very similar to the sharpening of diffraction peaks from a diffraction grating as the
10 number of slits increases. Of course, cutting large gratings to produce multiple smaller ones also has obvious manufacturing utility.

It should be noted that the examples in the figures herein have shown single gratings with no external components. In use there will, of course, be conventional external components such as a laser light source, and typically much more. Furthermore, in suitable applications
15 considerable benefit can be obtained by using multiple gratings and other components together. One of the particular strengths of micro fabrication type processes, as used by the present invention, is that they can be used to construct large numbers and varieties of components concurrently. Such products can then be used either in operational combination or separately. Thus, for example, multiple linear gratings **500**, planar gratings **600**, or cubical gratings **700** can
20 be constructed together in a linear or other operational arrangement, using different lattice dimensions, doping, etc. to work with different light wavelengths. If desired, other electrical and micro-mechanical components can also be constructed in the same substrate or in the same layer materials, e.g., one or more electro-optical sensors or micro mirrors. The present invention is thus very highly integrateable with IC and MEMS technology.

25 While various embodiments have been described above, it should be understood that they have been presented by way of example only, and not limitation. Thus, the breadth and scope of the invention should not be limited by any of the above described exemplary embodiments, but should be defined only in accordance with the following claims and their equivalents.

INDUSTRIAL APPLICABILITY

The present invention is well suited for application in the production of linear, planar, and cubical optical gratings, with the latter, multi-dimensional types being particularly novel and exhibiting potential for application in manners heretofore not possible in the art.

The invention may be produced using processes common in mature arts like semiconductor manufacturing. For example, micro fabrication process such as photolithography, etching, thin film deposition, doping, stripping, thermal annealing, chemical mechanical polishing (CMP), planarization, etc., which are common in the production of electronic integrated circuits and micro electro-mechanical systems, may now also be used to produce the inventive optical gratings in or atop substrate materials such as glass plate or silicon wafer.

These mass-production process well produce miniature devices with great accuracy, as the two common examples of 256MB DRAM and high-speed microprocessors illustrate. Such semiconductor type manufacturing process have an amazing dimension control, being able to readily produce devices with line widths as small as 0.1 micron and trench depths of 10 microns. As has been described, above, these semiconductor-type process also allow gratings to be made in a single dimension, two dimensions, and even three dimensions.

Accordingly, the invention may employ the many benefits of such generally accepted technology in a field where such are highly desired. The invention provides a marked departure from traditional and fiber-based optical grating technology known today, and particularly from conventional Bragg grating technology. In particular, compared to prior grating technologies, the invention is low cost. The inventive gratings can be economically mass-produced, like integrated circuits presently are.

The inventive gratings may be made very compact, and thus they can be easily attached to optical fibers or laser light sources directly. This avoids much of the awkwardness of handling and interfacing, and poor robustness of traditional gratings. Furthermore, the inventive gratings may be highly durable, and thus able to survive broader temperature and humidity ranges than conventional fiber-type Bragg gratings. The inventive gratings are also absolute devices, and since the dimensions are very accurately made, the absolute wavelength that is in "resonance" with the pitch of the grating can be known immediately. As has also been described, the semiconductor-type process used also allow the present inventive gratings to be very highly

integrateable with IC and MEMS technology, to construct larger useful systems.

For the above, and other reasons, it is expected that the process and products of the present invention will have widespread industrial applicability. Therefore, it is expected that the commercial utility of the present invention will be extensive and long lasting.

MULTIDIMENSIONAL OPTICAL GRATINGS

Inventors: WANG, David W.; and TSAI John C.

Atty. ref.: 60617.300801

THIS CORRESPONDENCE CHART IS FOR EASE OF UNDERSTANDING AND INFORMATIONAL PURPOSES ONLY, AND DOES NOT FORM A PART OF THE FORMAL PATENT APPLICATION.

1	fiber Bragg grating	232	transmissive layer
2	grating region	240	light beam
3	interlayer	242	strayed portions
4	laser beam	244	interface
5	reflected beam	246	interface
6	passed beam	248	reflected portion
		250	passed portion
100	Bragg grating		
102	laser beam	302	substrate
104	substrate	304	grating region
106	reflective layer	306	mask
108	grating region	308	grating pattern
110	interlayer	310	interlayer array
112	first transmissive material	400	process
114	second transmissive material	402-412	steps
116	over-fill layer	422-462	sub-steps
118	reflected beam		
120	passed beam	500	linear grating
		502	background material
202	substrate	504	interlayer material
204	photoresist layer	506	thickness
204a	unexposed region	508	separation
204b	exposed region	510	light beam
206	photomask	512	reflected beam
208	pre-designated pattern	514	passed beam
212	light		
214	transmissive layer	600	planar grating
216	air gap	602	background
218	photoresist layer	604	cells
218a	unexposed region	606	XYZ-axes icon
218b	exposed regions	608	thickness
220	photomask	610	separation
222	grating pattern	612	thickness
224	light	614	separation
226	grating region	616	light beam
228	over-fill layer	618	diffracted beam
230	interlayer array	620	passed beam

700	cubical grating	822	second refracted portion
702	background	826	vertical separation
704	cells	828	horizontal separation
706	XYZ-axes icon	830	vertical separation
708	light beam	850	grating
710	first diffracted beam	852	background
712	second diffracted beam	854	cells
714	passed beam	856	horizontal thickness
		858	vertical thickness
800	generic grating	860	horizontal separation
802	background	862	first vertical separation
804	cell	864	second vertical separation
806	thickness	866	first portions
808	light beam	868	second portions
810	first surface		
812	first reflected portion	880	grating
814	first refracted portion	882	cells
816	second surface	884	first portions
818	second reflected portion	886	second portions
820	transmitted portion	888	third portions
